

Square root of 147 simplified

A square root of a number is a number that, when it is multiplied by itself (squared), gives the first number again. For example, 2 is the square roots. A number bigger than zero have real square roots is positive (bigger than zero) and the other is negative (smaller than zero). For example, 4 has two square roots: 2 and -2. The only square root of zero is zero. A whole number is called a perfect square root radical is simplified or in its simplest form only when the radicand has no square factors left. A radical is also in simplest form when the radicand is not a fraction. In linear algebra, the Cholesky decomposition or Cholesky factorization (pronounced /[ə'lɛski/ shə-LES-kee) is a decomposition of a Hermitian, positive-definite matrix and its conjugate transpose, which is useful for efficient numerical solutions, e.g., Monte Carlo simulations. It was discovered by André-Louis Cholesky for real matrices. When it is applicable, the Cholesky decomposition is roughly twice as efficient as the LU decomposition for solving systems of linear equations.[1] Statement The Cholesky decomposition of a Hermitian positive-definite matrix A, is a decomposition of the form A = L L * , {\displaystyle \mathbf {A} =\mathbf {LL} ^{*},} where L is a lower triangular matrix with real and positive-definite matrix) has a unique Cholesky decomposition.[2] The converse holds trivially: if A can be written as LL* for some invertible L, lower triangular or otherwise, then A is a real matrix (hence symmetric positive-definite), the factorization may be written A = L L T, {\displaystyle \mathbf {L} ^{{\mathbf }}, where L is a real lower triangular matrix with positive diagonal entries.[3][4][5] Positive semidefinite matrices If a Hermitian matrix A is only positive semidefinite, instead of positive definite, then it still has a decomposition of the form A = LL* where the diagonal entries of L are allowed to be zero.[6] The decomposition need not be unique, for example: [0001] = LL*, L = [00 cos θ sin θ]. {\displaystyle $begin{bmatrix}0&0\cos\theta \end{bmatrix}. However, if the rank of A is r, then there is a unique lower triangular L with exactly r positive diagonal elements and n-r columns containing all zeroes. [7] Alternatively, the$ decomposition can be made unique when a pivoting choice is fixed. Formally, if A is an n × n positive semidefinite matrix of rank r, then there is at least one permutation matrix P such that P A PT = L L* with L = [L 1 0 L 2 0] {\displaystyle \mathbf{L} = {\begin{bmatrix} mathbf{L} = {\begin{bmatrix} mathbf{matrix} mathbf{L} = {\begin{bmatrix} mathbf{matrix} math {L} _{2}&0\end{bmatrix}}}, where L1 is an r × r lower triangular matrix with positive diagonal.[8] LDL decomposition A closely related variant of the classical Cholesky decomposition, A = L D L *, {\displaystyle \mathbf {LDL} ^{*}, } where L is a lower unit triangular (unitriangular) matrix, and D is a diagonal matrix. That is, the diagonal elements of L are required to be 1 at the cost of introducing an additional diagonal matrix D in the decomposition can be computed and used with essentially the same algorithms, but avoids extracting square roots.[9] For this reason, the LDL decomposition is often called the square-root-free Cholesky decomposition. For real matrices, A = QAQT. The LDL decomposition is related to the classical Cholesky decomposition of the form LL* as follows: $A = L D 1 / 2 (D 1 / 2) * L * = L D 1 / 2 (L D 1 / 2) * L * = L D 1 / 2 (L D 1 / 2) * L * = L D 1 / 2 (L D 1 / 2) * . {\displaystyle \mathbf {L} \nathbf {$ $d = 1 \ L = 0 \ L =$ decomposition exists where the number of non-zero elements on the diagonal D is exactly the rank of A.[10] Some indefinite matrices for which no Cholesky decomposition exists have an LDL decomposition exist have an LDL deco decomposition of a symmetric real matrix: (4 12 - 16 12 37 - 43 - 16 - 43 98) = (2 0 0 6 1 0 - 8 5 3)(2 6 - 8 0 1 5 0 0 3). {\displaystyle {\begin{array}} + {3}{r}} + {2}&0&0() & {2}&0 - 8 0 1 5 0 0 3). {\displaystyle {\begin{array}} + {3}{r}} ${3}{r}^2 = (100310 - 451)(40001009)(13 - 4015001).$ decomposition is mainly used for the numerical solution of linear equations $A = b \left(\frac{x + (displaystyle \mathbf {b} }{b} \right)$. If A is symmetric and positive definite, then we can solve $A = b \left(\frac{x + (displaystyle \mathbf {b} }{b} \right)$. $\{*\}\}$, then solving L y = b {\displaystyle \mathbf {L} } for y by forward substitution, and finally solving L * x = y {\displaystyle \mathbf {V}} for x by back substitution. An alternative way to eliminate taking square roots in the L L * {\displaystyle \mathbf {L} ^{ \mathbf{k} } b } for y by forward substitution is to compute the Cholesky decomposition $A = L D L * \{ (displaystyle (mathbf {L}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathbf {DL}) ^{(mathrm {*} }), then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathbf {DL}) ^{(mathrm {*})}, then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathrm {*})}, then solving D L * x = y {(displaystyle (mathbf {DL}) ^{(mathbf {DL}) ^{(mathrm {*})}, then solving D L * x = y {(displaystyle (m$ decomposition (or its LDL variant) is the method of choice, for superior efficiency and numerical stability. Compared to the LU decomposition, it is roughly twice as efficient.[1] Linear least squares Systems of the form Ax = b with A symmetric and positive definite arise quite often in applications. For instance, the normal equations in linear least squares problems are of this form. It may also happen that matrix A comes from an energy functional, which must be positive from physical considerations; this happens frequently in the numerical solution of partial differential equations. Non-linear multi-variate functions may be minimized over their parameters using variants of Newton's method called quasi-Newton methods. At iteration k, the search steps in a direction p k {\displaystyle p_{k}} for p k {\displaystyle p_{k}} is the step direction, g k {\displaystyle p_{k}} is the gradient, and B k {\displaystyle B_{k}} is the gradient, and B k {\displaystyle B_{k}} is the step direction, g k {\displaystyle p_{k}} is the gradient, and B k {\displaystyle B_{k}} is the gradient is the gra an approximation to the Hessian matrix formed by repeating rank-1 updates at each iteration. Two well-known update formulas are called Davidon-Fletcher-Goldfarb-Shanno (BFGS). Loss of the positive-definite condition through round-off error is avoided if rather than updating an approximation to the inverse of the Hessian, one updates the Cholesky decomposition of the Hessian matrix itself.[12] Monte Carlo simulating systems with multiple correlated variables. The covariance matrix is decomposed to give the lower-triangular L. Applying this to a vector of uncorrelated samples u produces a sample vector Lu with the covariance properties of the system being modeled.[13] The following simplified example shows the economy one gets from the Cholesky decomposition: suppose the goal is to generate two correlated normal variables x 1 {\displaystyle x {1}} and x 2 {\displaystyle x {2}} with given correlation coefficient ρ {\displaystyle x {1}} and z 2 {\displaystyle z {1}} and z 2 {\displaystyle x {2}}. variables can be obtained via the transformations x 1 = z 1 {\displaystyle $x_{1}=z_{1}$ and $x 2 = \rho z 1 + 1 - \rho 2 z 2$ {\textstyle $x_{2}=\rbo z_{1}+1-\rho 2 z 2$ {\textstyle $x_{2}=\rbo z_{2}+1-\rho 2$ system as a vector x of length N and covariance as an N × N matrix P. The matrix P is always positive semi-definite and can be decomposed into LLT. The columns of L can be added and subtracted from the mean x to form a set of 2N vectors called sigma points. These sigma points completely capture the mean and covariance of the system state. Matrix inversion The explicit inverse of a Hermitian matrix can be computed by Cholesky decomposition, in a manner similar to solving linear systems, using n 3 {\displaystyle 1^{2} } multiplications).[9] The entire inversion can even be efficiently performed in-place. A non-Hermitian matrix B can also be inverted using the following identity, where BB* will always be Hermitian: B - 1 = B * (BB *) - 1. {\displaystyle \mathbf {B} ^{*}(\mathbf {B} ^{*})^{-1}.} Computation There are various methods for calculating the Cholesky decomposition. The computational complexity of commonly used algorithms is O(n3) in general.[citation needed] The algorithms described below all involve about (1/3)n3 FLOPs (n3/6 multiplications and the same number of additions) for real flavors, [14] where n is the size of the matrix A. Hence, they have half the cost of the LU decomposition, which uses 2n3/3 FLOPs (see Trefethen and Bau 1997). Which of the algorithms below is faster depends on the details of the implementation. Generally, the first algorithm will be slightly slower because it accesses the data in a less regular manner. The Cholesky algorithm will be slightly slower because it accesses the data in a less regular manner. recursive algorithm starts with i := 1 and A(1) := A. At step i, the matrix A(i) has the following form: A(i) = (Ii - 1000 a i, ibi * 0bi B(i)), {\displaystyle \mathbf {B} {i}^{(i)} = (Varther index in matrix of dimension i - 1. If we now define the matrix Li by Li := (Ii - 1000 ai, i001 ai, i01 ai, ibiIn - i), {\displaystyle \mathbf{L}_{i}:={\begin{pmatrix}} + 1) Li * $displaystyle \\ 1 \in \{1, 1\} \\$ {i}^{*}\end{pmatrix}}.} Note that bi b*i is an outer product, therefore this algorithm is called the outer-product version in (Golub & Van Loan). We repeat this for i from 1 to n. After n steps, we get A(n+1) = I. Hence, the lower triangular matrix L we are looking for is calculated as L := L 1 L 2 ... L n . {\displaystyle \mathbf {L} :=\mathbf {L} {1} mathbf {L} {1} mathbf {L} {1} mathbf {L} {1} The Cholesky-Banachiewicz algorithms Access pattern (white) and writing pattern (white) and w 11 2 (symmetric) L 21 L 11 L 21 2 + L 22 2 L 31 L 11 L 31 L 21 + L 32 L 22 L 31 2 + L 32 2 + L 33 2), {\displaystyle {\begin{aligned}\mathbf{A} = \mathbf{L} ^{T}&={\begin{pmatrix}L {11}&0&0\\L {21}&L {22}&0\\L {31}&L {32}&L {33}\\\end{pmatrix}} following: L = (A 11 0 0 A 21 / L 11 A 22 - L 21 2 0 A 31 / L 11 (A 32 - L 31 L 21) / L 22 A 33 - L 31 2 - L 32 2) {\displaystyle {\begin{aligned}\mathbf{L} = {\begin{aligned}\mathbf{L} = {\begin{begin{aligned}\call{l}} + L {21} - L {21} - {2}} & {\call{l}} + L {21} + {\call{l}} & {\call{l}} + L {21} + {\call{l}} & {\call{l}} + L {21} + {\call{l}} & {\call{l}} + L {21} + L {21} + {\call{l}} & {\call{l}} & {\call{l}} + L {21} + {\call{l}} & { $L {32}^{2}} = 1 j - 1 L j, j = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}=(pm) {sqrt {A_{j,j}-}sum {k=1}^{j-1}L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - \Sigma k = 1 j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm) A j, j - 1 L j, k 2, {displaystyle L {j,j}} = (\pm)$ [k=1}^{j-1}L_{i,k}L_{j,k}\right)\quad {\text{for }}i>j.} For complex and real matrices, inconsequential arbitrary sign changes of diagonal elements are allowed. The expression under the square root is always positive if A is real and positive-definite. For complex Hermitian matrix, the following formula applies: L j , j = A j, j - $\sum k = 1 j - 1 L j$, k L j, k *, {\displaystyle L {j,j}={\sqrt {A {j,j}-\sum {k=1}^{j-1}L {j,k}_L {j,k}^{*}}}, L i, j = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} \left(A {i,j}-\sum {k=1}^{j-1}L {j,k}_L {j,k}^{*}}) = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} \left(A {i,j}-\sum {k=1}^{j-1}L {j,k}_L {j,k}^{*}}) = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - $\sum k = 1 j - 1 L i$, k L j, k *) for i > j. {\displaystyle L {j,j}} = 1 L j, j (A i, j - (A know the entries to the left and above. The computation is usually arranged in either of the following orders: The Cholesky-Banachiewicz algorithm starts from the upper left corner of the matrix L and proceeds to calculate the matrix row by row. for (i = 0; i < dimensionSize; i++) { for (j = 0; j
